## Summary

- As climate change is driving increased drought frequency and severity in many forested regions around the world, mechanistic understanding of the factors conferring drought resistance in trees is increasingly important. The dendrochronological record provides a window through which we can understand how tree size and species' traits shape tree growth responses during droughts.
- We analyzed tree-ring records for twelve species that comprise 97% of the woody productivity of the 25.6-ha ForestGEO plot in a broadleaf deciduous forest of northern Virginia (USA) to test hypotheses on how tree height, microenvironment characteristics, and species' traits shaped drought responses across the three strongest regional droughts over a 60-year period (1950 - 2009).
- Individual-level drought resistance decreased with tree height, which was overall a stronger predictor than crown exposure. The potentially greater rooting volume of larger trees did not confer an advantage in sites with low topographic wetness index. Resistance was greater among species whose leaves experienced less shrinkage upon desiccation and lost turgor (wilted) at more negative water potentials.
- We conclude that tree height and hydraulic traits influence growth responses during drought, as recorded in the tree-ring record spanning historical droughts. Thus, these factors can be useful for predicting future drought responses under climate change.

*Key words:* annual growth; crown exposure; drought; Forest Global Earth Observatory (ForestGEO); leaf hydraulic traits; temperate broadleaf deciduous forest; tree height; tree-ring

## Introduction

Forests play a critical global role in climate regulation (Bonan, 2008), yet there remains enormous uncertainty as to how the terrestrial carbon sink, which is dominated by forests, will respond to climate change (Friedlingstein et al., 2006). An important aspect of this uncertainty lies with physiological responses of trees to drought (Kennedy et al., 2019). In many forested regions around the world, the risk of severe drought is increasing (Trenberth et al., 2014; Dai et al., 2018), often despite increasing precipitation (Intergovernmental Panel on Climate Change, 2015; Cook et al., 2015). Droughts, intensified by climate change, have been affecting forests worldwide and are expected to continue as one of the most important drivers of forest change in the future (Allen et al., 2010, 2015). Understanding forest responses to drought requires elucidation of how tree size, microenvironment, and species’ traits jointly influence individual-level drought resistance, and the extent to which their influence is consistent across droughts. However, it has proven difficult to resolve the many factors affecting tree growth during drought with available forest census data, which only rarely captures extreme drought, and with tree-ring records, which capture multiple droughts but rarely consider the roles of tree size and microenvironment.

Many studies have shown that within species, large trees tend to be more affected by drought. Greater growth reductions for larger trees was first shown on a global scale by Bennett et al. (2015), and subsequent studies have reinforced this finding (*e.g.*, Stovall et al. (2019); Hacket-Pain et al. (2016)). It has yet to be resolved which of several potential underlying mechanisms most strongly shape size trends in drought response. First, tree height may be a primary driver. Taller trees face the biophysical challenge of lifting water greater distances against the effects of gravity and friction (McDowell et al., 2011; McDowell and Allen, 2015; Ryan et al., 2006; Couvreur et al., 2018). Vertical gradients in stem and leaf traits—including smaller and thicker leaves (higher leaf mass per area, LMA), greater resistance to hydraulic dysfunction (*i.e.*, more negative water potential at 50% loss of hydraulic conductivity, more negative P50), and lower hydraulic conductivity at greater heights (Couvreur et al., 2018; Koike et al., 2001; McDowell et al., 2011)—enable trees to become tall (Couvreur et al., 2018). Indeed, tall trees require xylem of greater hydraulic efficiency, such that xylem conduit diameters are wider in the basal portions of taller trees, both within and across species (Olson et al., 2018; Liu et al., 2019), and throughout the conductive systems of angiosperms (*Zak et al. 2010, Olson et al. 2014, 2018*). Wider xylem conduits plausibly make large trees more vulnerable to embolism during drought (Olson et al., 2018), and traits conducive to efficient water transport may also lead to poor ability to recover from or re-route water around embolisms (Roskilly et al., 2019). Second, larger trees may have lower drought resistance because their crowns tend to occupy more exposed canopy positions, where they experience higher solar radiation, greater wind speeds, and lower relative humidity (**REFS-KAT**). Subcanopy trees tend to fare better specifically due to the benefits of a buffered environment (Pretzsch et al., 2018). Third, large trees tend to have larger root systems, which potentially counteracts some of the biophysical challenges they face by allowing greater access to water; however, it appears that this effect is usually insufficient to offset the costs of height and/or crown exposure. Finally, tree size-related responses to drought can be modified by species’ traits and their distribution across size classes (Meakem et al., 2018; Liu et al., 2019). Understanding the mechanisms driving the greater relative growth reductions of larger trees during drought will require sorting out the interactive effects of height, crown position, root water access, and species’ traits.

Debates have also arisen regarding the traits influencing tree growth responses to drought. Studies in temperate broadleaf forests have observed that ring-porous species showing higher drought tolerance than

diffuse-porous species (Friedrichs et al., 2009; Elliott et al., 2015; Kannenberg et al., 2019), but this distinction would not hold in the global context (Wheeler et al. 2007, Olson et al. 2020) and does not resolve differences among the many species within each category. Commonly-measured traits including wood density and leaf mass per area ( $LMA$ ) have been linked to drought responses in some temperate deciduous forests (Abrams, 1990; Guerfel et al., 2009; Hoffmann et al., 2011; Martin-Benito and Pederson, 2015) and other forest biomes around the world (Greenwood et al., 2017). However, in other cases these traits could not explain drought tolerance (Maréchaux et al., 2019), or the direction of response was not always consistent. For instance, higher wood density has been associated with greater drought resistance at a global scale (Greenwood et al., 2017), but it correlated negatively with tree performance during drought in a broadleaf deciduous forest in the southeastern United States (Hoffmann et al., 2011). Thus, the perceived influence of these traits on drought resistance may actually reflect indirect correlations with other traits that more directly drive drought responses (Hoffmann et al., 2011). Recent work has shown a great potential for hydraulic traits to predict growth and mortality responses. Hydraulic traits including water potentials at which percent loss of conductivity surpass a certain threshold ( $P50$ ,  $P80$ ,  $P88$ ) and hydraulic safety margin correlate with drought performance (Anderegg et al., 2018) but are time-consuming to measure and therefore infeasible for predicting or modeling drought responses in highly diverse forests (*e.g.*, in the tropics). More easily measurable leaf hydraulic traits with direct linkage to plant hydraulic function can explain greater variation in plant distribution and function (Medeiros et al., 2019). These include leaf area shrinkage upon desiccation ( $PLA_{dry}$ ) (Scoffoni et al., 2014) and the leaf water potential at turgor loss point ( $\pi_{tlp}$ ), *i.e.*, the water potential at which leaf wilting occurs (Bartlett et al., 2016). The abilities of both  $PLA_{dry}$  and  $\pi_{tlp}$  to explain tree performance under drought remains untested.

Here, we examine how tree height, microenvironment characteristics, and species' traits collectively shape drought responses. We test a series of hypotheses and associated specific predictions (Table 1) based on the combination of tree-ring records from three droughts (1966, 1977, 1999), species functional and hydraulic trait measurements, and census data from a large forest dynamics plot in Virginia, USA (Table 2). First, we focus on the role of tree height and its interaction with microenvironment. We test hypotheses designed to disentangle the relative importance of tree height; crown exposure; and soil water availability, which should be greater for larger trees in dry but not in perpetually wet microsites. Second, we focus on the role of species' functional and hydraulic traits, testing the hypothesis that species' traits—particularly leaf hydraulic traits—predict  $Rt$ . We test predictions that drought resistance is higher in ring-porous than semi-ring and diffuse-porous species, that it is correlated with wood density—either positively (Greenwood et al., 2017) or negatively (Hoffmann et al., 2011)—and positively correlated with  $LMA$ , and that hydraulic leaf traits including  $PLA_{dry}$  and  $\pi_{tlp}$  are better predictors.

## Materials and Methods

### Study site

Research was conducted at the 25.6-ha ForestGEO (Forest Global Earth Observatory) study plot at the Smithsonian Conservation Biology Institute (SCBI) in Virginia, USA (38°53'36.6"N, 78°08'43.4"W; Fig. S1) (Bourg et al., 2013; Anderson-Teixeira et al., 2015a). SCBI is located in the central Appalachian Mountains near the northern boundary of Shenandoah National Park. Elevations range from 273 to 338 m above sea level with a topographic relief of 65m (Bourg et al., 2013). Climate is humid temperate, with mean annual temperature of 12.7°C and precipitation of 1005 mm during our study period (1960-2009; source: CRU TS

v.4.01; Harris et al. (2014)). Dominant tree taxa within this secondary forest include *Liriodendron tulipifera*, oaks (*Quercus* spp.), and hickories (*Carya* spp.; Table 3).

#### Identifying drought years

We identified the three largest droughts within the time period 1950-2009, defining drought (Slette et al., 2019) as events with anomalously dry peak growing season climatic conditions. Specifically, we used the metric of Palmer Drought Severity Index (PDSI) during May-August (MJJA; Table S3), which were identified by Helcoski et al. (2019) as the months of the current year to which annual tree growth was most sensitive at this site. PDSI divisional data for Northern Virginia were obtained from NOAA (<https://www7.ncdc.noaa.gov/CDO/CDODivisionalSelect.jsp>) in December 2017. Based on this, we identified three drought years - 1966, 1977, and 1999 (Figs. 1, S2, Table S3).

The droughts differed in intensity and antecedent moisture conditions (Fig. S2, Table S3). The 1966 drought was preceded by two years of moderate drought during the growing season and severe to extreme drought starting the previous fall and in August reached the lowest growing season *PDSI* (-4.82) of the three droughts. The 1977 drought was the least intense throughout the growing season, and it was preceded by 2.5 years of near-normal conditions, making it the mildest of the three droughts. The 1999 drought was preceded by wetter than average conditions until the previous June, but reached the lowest *PDSI* during May-July (-4.53).

#### Data collection and preparation

Within or just outside the ForestGEO plot, we collected data on a suite of variables including tree size, microenvironment characteristics, and species traits (Table 2). The SCBI ForestGEO plot was censused in 2008, 2013, and 2018 following standard ForestGEO protocols, whereby all free-standing woody stems  $\geq 1$ cm diameter at breast height (DBH) were mapped, tagged, measured at DBH, and identified to species (Condit, 1998). From this census data, we used measurements of DBH from 2008 to calculate historical DBH and data for all stems  $\geq 10$ cm to analyze functional trait composition relative to tree height (all analyses described below). Census data are available through the ForestGEO data portal ([www.forestgeo.si.edu](http://www.forestgeo.si.edu)).

We analyzed tree-ring data (xylem growth increment) from 571 trees representing the twelve species with the greatest contributions to woody aboveground net primary productivity ( $ANPP_{stem}$ ), which together comprised 97% of study plot  $ANPP_{stem}$  between 2008 and 2013 (Helcoski et al., 2019) (Table 3; Fig. S1). Cores (one per tree) were collected within the ForestGEO plot at breast height (1.3m) in 2010-2011 or 2016-2017. In 2010-2011, cores were collected from randomly selected live trees of each species that had at least 30 individuals  $\geq 10$  cm DBH (Bourg et al., 2013). In 2016-2017, cores were collected from all trees found dead during annual mortality censuses (Gonzalez-Akre et al., 2016). Cores were sanded, measured, and crossdated using standard procedures, as detailed in (Helcoski et al., 2019). The resulting chronologies (Fig. 1a) were published in Zenodo (DOI: 10.5281/zenodo.2649302) in association with Helcoski et al. (2019).

For each cored tree, we combined tree-ring records and allometric equations of bark thickness to reconstruct DBH for the years 1950-2009. Prior *DBH* was estimated using the following equation:

$$DBH_Y = DBH_{2008} - 2 * \left[ \sum_{year=Y}^{2008} (r_{ring,Y}) - r_{bark,Y} + r_{bark,2008} \right]$$

Here,  $Y$  denotes the year of interest,  $r_{ring}$  denotes ring width derived from cores, and  $r_{bark}$  denotes bark thickness. Bark thickness was estimated from species-specific allometries based on the bark thickness data from the site (Anderson-Teixeira et al., 2015b). Specifically, we used linear regression on log-transformed data to relate  $r_{bark}$  to diameter inside bark from 2008 data (Table S1), which were then used to determine  $r_{bark}$  in the  $DBH$  reconstruction.

Tree heights ( $H$ ) were measured by several researchers for a variety of purposes between 2012 to 2019 (n=1,518 trees). Measurement methods included direct measurements using a collapsible measurement rod on small trees (NEON, 2018) or a tape measure on recently fallen trees (this study); geometric calculations using clinometer and tape measure (Stovall et al., 2018a) or digital rangefinders (Anderson-Teixeira et al., 2015b; NEON, 2018); and ground-based LiDAR (Stovall et al., 2018b). Rangefinders used either the tangent method (Impulse 200LR, TruPulse 360R) or the sine method (Nikon ForestryPro) for calculating heights. Both methods are associated with some error (Larjavaara and Muller-Landau, 2013), but in this instance there was no clear advantage of one or the other. Measurements from the National Ecological Observatory Network (NEON) were collected near the ForestGEO plot following standard NEON protocol, whereby vegetation of short stature was measured with a collapsible measurement rod, and taller trees with a rangefinder (NEON, 2018). Species-specific height allometries were developed (Table S2) using logarithmic regression ( $\ln[H] \sim \ln[DBH]$ ). For species with insufficient height data to create reliable species-specific allometries (n=2, JUNI and FRAM), heights were calculated from an equation developed by combining the height measurements across all species. We then used these allometries to estimate  $H$  for each drought year,  $Y$ , based on reconstructed  $DBH_Y$ .

Crown position—a categorical variable including dominant, co-dominant, intermediate, and suppressed—was recorded for all cored trees that remained standing during the growing season of 2018 following the protocol of Jennings et al. (1999). While some tree crowns undoubtedly changed position over the past several decades, in this case the bias would be unlikely to result in false acceptance of the prediction that dominant trees have the lowest  $Rt$  (*i.e.*, type I error unlikely, type II error possible), making our hypothesis test conservative. An analysis of crown position relative to height (Fig. 2d) and height changes since the beginning of the study period indicated that changes between focal drought years (1966, 1977, and 1999; see below) were fairly small relative to differences among crown positions (Fig. S3), with average tree height growth confined to ~0.82 m from 1966 to 1977, ~1.45 m from 1977 to 1999, and ~1.97 m from 1999 to 2018. However, dominant and co-dominant trees were similar in height (Figs. 2d, S3).

Topographic wetness index (TWI) was calculated using the dynatopmodel package in R (Fig. S1) (?). Originally developed by Beven and Kirkby (1979), TWI was part of a hydrological run-off model and has since been used for a number of purposes in hydrology and ecology (Sørensen et al., 2006). TWI calculation depends on an input of a digital elevation model (DEM; ~3.7 m resolution from the elevatr package (?)), and from this yields a quantitative assessment defined by how “wet” an area is, based on areas where run-off is more likely. From our observations in the plot, TWI performed better at categorizing wet areas than the Euclidean distance from the stream.

Hydraulic traits were collected in August 2018 (Tables 2-3; Fig. S4). We sampled small sun-exposed branches up to eight meters above ground from three individuals of each species in and around the ForestGEO plot. Sampled branches were re-cut under water at least two nodes above the original cut and re-hydrated overnight in covered buckets under opaque plastic bags before measurements were taken. Rehydrated leaves taken towards the apical end of the branch (n=3 per individual: small, medium, and

large) were scanned, weighed, dried at 60° C for  $\geq 48$  hours, and then re-scanned and weighed. Leaf area was calculated from scanned images using the LeafArea R package (Katabuchi, 2019).  $LMA$  was calculated as the ratio of leaf dry mass to fresh area.  $PLA_{dry}$  was calculated as the percent loss of area between fresh and dry leaves. Wood density was calculated for  $\sim 1$ cm diameter stem samples (bark and pith removed) as the ratio of dry weight to fresh volume, which was estimated using Archimedes' displacement. We used the rapid determination method of Bartlett et al. (2012) to estimate osmotic potential at turgor loss point ( $\pi_{tlp}$ ). Briefly, two 4 mm diameter leaf discs were cut from each leaf, tightly wrapped in foil, submerged in liquid nitrogen, perforated 10-15 times with a dissection needle, and then measured using a vapour pressure osmometer (VAPRO 5520, Wescor, Logan, UT, USA). Osmotic potential ( $\pi_{osm}$ ) given by the osmometer was used to estimate ( $\pi_{tlp}$ ) using the equation  $\pi_{tlp} = 0.832\pi_{osm}^{-0.631}$  (Bartlett et al., 2012).

To characterize how environmental conditions vary with height, data were obtained from the NEON tower located  $<1$ km from the study area via the neonUtilities package (?). We used wind speed, relative humidity, and air temperature data, all measured over a vertical profile spanning heights from 7.2 m to above the top of the tree canopy (31.0 or 51.8m, depending on censor), for the years 2016-2018 (NEON, 2018). After filtering for missing and outlier values, we determined the daily minima and maxima, which we then aggregated at the monthly scale.

### Statistical Analysis

For each drought year, we calculated drought resistance ( $Rt$ ) as the ratio of basal area increment ( $BAI$ ) during drought to the mean  $BAI$  over the five years preceding the drought (Lloret et al., 2011). Thus,  $Rt$  values  $<1$  and  $>1$  indicate growth reductions and increases, respectively. Because the  $Rt$  metric could be biased by directional pre-drought growth trends, we also tried an intervention time series analysis (ARIMA, (?)) that predicted mean drought-year growth based on trends over the past ten years and used this value in place of the five-year mean in calculations of resistance ( $Rt_{ARIMA}$  = observed  $BAI$  / predicted  $BAI$ ). The two metrics were strongly correlated (Fig. S5). Because  $Rt$  tended to produce more reasonable estimates than  $Rt_{ARIMA}$  when there was a large difference between these metrics, we selected  $Rt$  as our focal metric, presenting parallel results for  $Rt_{ARIMA}$  in the Supplementary Info. We focus exclusively on drought resistance ( $Rt$  or  $Rt_{ARIMA}$ ), and not on the resilience metrics described in Lloret et al. (2011), because (1) we would expect resilience to be controlled by a different set of mechanisms, and (2) the findings of DeSoto et al. (2020) suggest that  $Rt$  is a more important drought response metric for angiosperms.

Analyses focused on testing the predictions presented in Table 1, with  $Rt$  (or  $Rt_{ARIMA}$ ) as the response variable. Models were run for all drought years combined and for each drought year individually. The general statistical model for hypothesis testing was a mixed effects model, implemented in the lme4 package in R [REF], with  $Rt$  (or  $Rt_{ARIMA}$ ) as the response variable, tree nested within species as a random effect, and independent variables as specified below. In the multi-year model only, we also included a fixed effect of drought year. (IAN, CONFIRM THIS)) We used AICc to assess model selection, and conditional/marginal R-squared to assess model fit as implemented in the AICcmodavg package in R (?). AICc refers to a corrected version of AICc, and is best suited for small data sizes (see Brewer et al., 2016).

To avoid over-fitting models with five species traits (Table 2) across only 12 species, we did not include all traits as fixed effects in a single GLMM, but rather conducted individual tests of each species trait to determine the relative importance and appropriateness for inclusion in the main model. These tests followed the model structure specified above, including  $\ln[H]$ ,  $TWI$ , and crown position in the null model. Trait

variables were considered appropriate for inclusion in the main model if they had a consistent direction of response across all droughts and if their addition to this null model lacking the trait improved fit (at  $\Delta AICc \geq 1.0$ ) in at least one drought year (Table S4). We note that the  $\Delta AICc \geq 1.0$  criterion is not a test of significance, but of whether the variable has enough influence to be considered as a *candidate* variable in full models.

We then determined the top full models for predicting  $Rt$  (or  $Rt_{ARIMA}$ ). To do so, we compared models with all possible combinations of candidate variables, including  $\ln[H]*TWI$  or crown position and  $TWI$ , and species traits as specified above. Crown position and  $\ln[H]$  were never considered in the same model because of high correlation (0.73) between the two variables. We identified the full set of models within  $\Delta AICc=2$  of the best model (that with lowest  $AICc$ ). When a variable appeared in all of these models and the sign of the coefficient was consistent across models, we viewed this as support for the acceptance/rejection of the associated prediction (Table 1). If the variable appeared in some but not all of these models, and its sign was consistent across models, we considered this partial support/rejection. In presentation of the results below, we note instances where the  $Rt_{ARIMA}$  model disagreed with the  $Rt$  model, but otherwise do not discuss the  $Rt_{ARIMA}$  model.

All analysis beyond basic data collection was performed using R version 3.5.3 (R Core Team, 2020). Other R-packages aside from those already listed were very helpful in conducting analyses. These are listed in the Supplementary Information. All data, code, and results are available through the SCBI-ForestGEO organization on GitHub (<https://github.com/SCBI-ForestGEO>: SCBI-ForestGEO-Data and McGregor\_climate-sensitivity-variation repositories), with static versions corresponding to data and analyses presented here archived in Zenodo (DOIs: 10.5281/zenodo.3604993 and [TBD], respectively).

## Results

### *Community-level and species' drought responses*

At the community level, cored trees showed substantial growth reductions in all three droughts, with a mean  $Rt$  of 0.86 in 1966 and 1999, and 0.84 in 1977 (Fig. 1b). Across the entire study period (1950-2009), the focal drought years were the three years with the largest fraction of trees exhibiting  $Rt \leq 0.7$ . Specifically, in each drought, roughly 30% of the cored trees had growth reductions of  $\geq 30\%$  ( $Rt \leq 0.7$ ): 29% in 1966, 32% in 1977, and 27% in 1999. However, some individuals exhibited increased growth, *i.e.*,  $Rt > 1.0$ : 26% of trees in 1966, 22% in 1977, and 26% in 1999.

Responses varied across species and by drought (Fig. 2). Averaged across all droughts,  $Rt$  was lowest in *Liriodendron tulipifera* (mean  $Rt = 0.66$ ) and highest in *Fagus grandifolia* (mean  $Rt = 0.99$ ).

### *Tree size, microenvironment, and drought resistance*

Taller trees showed stronger growth reductions during drought when evaluating the three drought years together and for 1966 individually (Table 1; Fig. 4). Specifically,  $\ln[H]$  appeared, with negative coefficient, in the best models and all top models (Tables S6-S7). For the 1977 drought,  $\ln[H]$  did not appear in the best model, but was included, with negative coefficient, among the top models—*i.e.*, models that were statistically indistinguishable ( $\Delta AICc < 2$ ) from the best model (Tables 1, S6-S7). For the 1999 drought,  $\ln[H]$  appeared in no top models for  $Rt$  and some top models, with positive coefficient, for  $Rt_{ARIMA}$ .

Crown position varied as expected with height (dominant > co-dominant > intermediate > suppressed), but

with substantial variation (Fig. 3d). Crown position was not included in any of the top models for all droughts or for 1966 individually (Table 1). It did, however, come out in the best models for 1977 and 1999 (Fig. 4; Table S6). When  $Rt_{ARIMA}$  was used as the response variable, crown position was never in a best model, and was included among the top models only for 1977 (Table S7). Crown position did not have a consistent influence: dominant trees had the lowest  $Rt$  (or  $Rt_{ARIMA}$ ) in 1977, but in 1999 intermediate and suppressed trees had lower  $Rt$  (Fig. 4; Tables S6-S7).

In the years for which we have vertical profiles in climate data (2016-2018), taller trees—or those in dominant crown positions—were generally exposed to higher evaporative demand during the peak growing season months (May-August; Fig. 3). Specifically, maximum daily wind speeds were significantly higher above the top of the canopy (40-50m) than within and below (10-30m) (Fig. 3a). Relative humidity was also somewhat lower during June-August, ranging from ~50-80% above the canopy and ~60-90% in the understory (Fig. 3b). Air temperature did not vary across the vertical profile (Fig. 3c).

$Rt$  had a significantly negative response to  $\ln[TWI]$  in all drought years combined and in 1977 and 1999 individually (Fig. 4, Table S6). When  $Rt_{ARIMA}$  was used as the response variable, the effect was significant in all drought years combined and in 1977, and a negative effect of  $\ln[TWI]$  was included in some of the models in 1966 and 1999 (Table S7). This negates the idea that trees in moist microsites would be less affected by drought. Nevertheless, we tested for a  $\ln[H] * \ln[TWI]$  interaction, a negative sign of which could indicate that smaller trees (with smaller rooting volume) are more susceptible to drought in drier microenvironments with a deeper water table. This hypothesis was rejected, as the  $\ln[H] * \ln[TWI]$  interaction was never significant, and had a positive sign in any top models in which it appeared (Tables 1, S6-S7). This term did appear, with positive coefficient, in the best  $Rt_{ARIMA}$  model for all years combined (Table S7).

#### *Species' traits and drought resistance*

Species traits... (Table 3, Fig. S4)

Wood density,  $LMA$ , and xylem porosity were all poor predictors of  $Rt$  (Tables 1, S4-S5). Wood density and  $LMA$  were never significantly associated with  $Rt$  in the single-variable tests and were therefore excluded from the full models. Xylem porosity was also excluded from the full models, as it had no significant influence for all droughts combined and had contrasting effects in the individual droughts: whereas ring-porous species had higher  $Rt$  than diffuse- and semi-ring-porous species in the 1966 and 1999 droughts, they had lower  $Rt$  in 1977 (Table S4). It is noteworthy that the two diffuse-porous species in our study, *Liriodendron tulipifera* and *Fagus grandifolia*, were at opposite ends of the  $Rt$  spectrum (Fig. 2), further refuting the idea that xylem porosity is a useful predictor of  $Rt$  in the context of this study.

In contrast,  $PLA_{dry}$ , and  $\pi_{tlp}$  were linked to drought responses (Fig. 4; Tables 1, S4-S7). Both had consistent signs across all droughts and explained modest amounts of variation ( $\Delta AICc > 1.0$ ) during at least one of the three droughts (Table S4), qualifying them as candidate variables for the full model.  $PLA_{dry}$  had a significant influence, with negative coefficient, in full models for the three droughts combined and for the 1966 drought individually (Fig. 4; Tables S6-S7). For 1977 and 1999, it was included, with negative coefficient, in some of the top models (Tables S6-S7).  $\pi_{tlp}$  was included, with negative coefficient, in the best model for all droughts combined and for the 1977 drought individually (Fig. 4; Table 5). It was included in some of the top models for 1999 (Tables S6-S7).

## Discussion

Tree height, microenvironment, and hydraulic traits shaped tree growth responses across three droughts at our study site (Table 1, Fig. 4). The greater susceptibility of larger trees to drought, similar to forests worldwide (Bennett et al., 2015), was driven primarily by their height (Stovall et al., 2019). The negative effect of height on  $Rt$  held after accounting for species' traits. We found only a marginal effect of crown exposure with inconsistent direction across two individual droughts. There was no evidence that soil water availability increased drought resistance; in contrast, trees in wetter topographic positions had lower  $Rt$  (Zuleta et al., 2017; Stovall et al., 2019), and the larger potential rooting volume of large trees provided no advantage in the drier microenvironments. Drought resistance was not linked to species'  $LMA$ , wood density, or xylem type (ring- vs. diffuse porous), but was negatively correlated with leaf hydraulic traits ( $PLA_{dry}$ ,  $\pi_{tlp}$ ). This is the first report to our knowledge linking  $PLA_{dry}$  and  $\pi_{tlp}$  to growth reduction during drought. The directions of these responses were consistent across droughts, supporting the premise that they were driven by fundamental physiological mechanisms. However, the strengths of each predictor varied across droughts (Fig. 4; Tables S6-S7), indicating that drought characteristics interact with tree size, microenvironment, and traits to shape which individuals are most affected. These findings advance our knowledge of the factors that make trees vulnerable to growth declines during drought—and, by extension, likely make them more vulnerable to mortality (Sapes et al., 2019).

The droughts considered here were of a magnitude that has occurred with an average frequency of approximately once every 10-15 years (Fig. 1a, Helcoski et al. (2019)) and had substantial but not devastating impacts on tree growth (Figs. 1b, 2). These droughts were classified as severe (1977) or extreme (1966, 1999) according to the PDSI metric and have been linked to tree mortality in the eastern United States (Druckenbrod et al., 2019); however, extreme, multiannual droughts or so-called “megadroughts” of the type that have triggered massive tree die-off in other regions (e.g., Allen et al. (2010); Stovall et al. (2019)) have not occurred in the Eastern United States within the past several decades (Clark et al., 2016). Of the droughts considered here, the 1966 drought, which was preceded by two years of dry conditions (Fig. S2), severely stressed a larger portion of trees (Fig. 1b). The tendency for large trees to have lowest resistance was most pronounced in this drought, consistent with other findings that this physiological response increases with drought severity (Bennett et al., 2015; Stovall et al., 2019). Across all three droughts, the majority of trees experienced reduced growth, but a substantial portion had increased growth (Fig. 1b), potentially due to decreased leaf area of competitors during the drought (REF—if we can find one), and consistent with prior observations that smaller trees can exhibit increased growth rates during drought (Bennett et al., 2015). It is likely because of the moderate impact of these droughts, along with other factors influencing tree growth (e.g., stand dynamics), that our best models characterize only a modest amount of variation in  $Rt$ : 11-12% for all droughts combined, and 18-25% for each individual drought (Table S6).

Our analysis indicates that tree height has an overall stronger influence on drought response than does crown position (Table 1). This is consistent with, and reinforces, previous findings that biophysical constraints make it impossible for trees to efficiently transport water to great heights and simultaneously maintain strong resistance and resilience to drought-induced embolism (Olson et al., 2018; Couvreur et al., 2018; Roskilly et al., 2019). However, the collinearity between the two variables (Fig. 3d) makes it impossible to confidently partition causality. Taller trees are more likely to be in dominant canopy positions (Fig. 3d) and, largely as a consequence of their position relative to others, face different microenvironments (Fig. 3a-b). Even under non-drought conditions, evaporative demand and maximum leaf temperatures increase with tree

height (Smith and Nobel, 1977; Bretfeld et al., 2018; Kunert et al., 2017), and such conditions would incur additional stress during drought, when solar radiation tends to be higher and less water is available for evaporative cooling of the leaves (*Campbell & Norman REF*). Previous studies have shown lower drought resistance in more exposed trees (Liu and Muller, 1993; Suarez et al., 2004; Scharnweber et al., 2019), and . . . However, some decoupling between height and crown position is introduced by the configuration of neighboring trees (Fig. 3d) (Muller-Landau et al., 2006), and height was an overall stronger predictor of drought response than crown position (Fig. 4; Tables 1). Belowground, taller trees would tend to have larger root systems, but the potentially greater access to water did not override the disadvantage conferred by height—and, in fact, greater moisture access in non-drought years (here, higher TWI) appears to make trees more sensitive to drought (Zuleta et al., 2017; Stovall et al., 2019).

*Our analysis has the limitation that crown positions were recorded in 2018, as opposed to the years of the droughts. However, because trees would generally advance towards more dominant positions as they grow and as neighbors die, changing crown positions would bias against the acceptance of our hypothesis. The implication is that dominant crown positions did have a marginally negative influence on  $R_t$ , which makes sense in light of the vertical environmental gradients described above and agrees with previous studies showing lower drought resistance in more exposed trees (Liu and Muller, 1993; Suarez et al., 2004; Scharnweber et al., 2019). It is safe to assume that currently suppressed trees were suppressed throughout our analysis period, and their relatively low  $R_t$  (after accounting for height effects) is real, perhaps as a result of competition (Sohn et al., 2016). The observed height-sensitivity of  $R_t$ , together with the lack of advantage to large stature in drier topographic positions, agrees with the concept that physiological limitations to transpiration under drought shift from soil water availability to the plant-atmosphere interface as forests age (Bretfeld et al., 2018), such that tall, dominant trees are the most sensitive in mature forests. Additional research comparing drought responses of young and old forest stands, along with short and tall isolated trees, would be valuable for more clearly disentangling the roles of tree height and crown exposure.*

The development of tree-ring chronologies for the twelve most dominant tree species at our site (Helcoski et al., 2019; Bourg et al., 2013) gave us the sample size to compare historical drought responses across species (Fig. 2) and associated traits at a single site (see also Elliott et al., 2015). Our study reinforced the findings of previous studies (see Introduction) that wood density and  $LMA$  are not reliably linked to drought resistance (Table 1). Contrary to previous studies in temperate deciduous forests, we did not find an association between xylem porosity and drought tolerance, as the two diffuse-porous species, *Liriodendron tulipifera* and *Fagus grandifolia*, were at opposite ends of the  $R_t$  spectrum (Fig. 2). While the low  $R_t$  of *L. tulipifera* is consistent with other studies (Elliott et al., 2015), the high  $R_t$  of *F. grandifolia* contrasts with studies identifying diffuse porous species in general (Elliott et al., 2015; Kannenberg et al., 2019), and the genus *Fagus* in particular (Friedrichs et al., 2009), as drought sensitive.

There are two potential explanations for this discrepancy. First, other traits can and do override the influence of xylem porosity on drought resistance. Ring porous species are restricted mainly to temperate deciduous forests (Wheeler et al. 2007), while highly drought-tolerant diffuse-porous species exist in other biomes (*REFS*). *Fagus grandifolia* had intermediate  $\pi_{tlp}$  and low  $PLA_{dry}$  (Fig. S4), which would have contributed to its drought resistance (Fig. 4; see discussion below). A second explanation of why *F. grandifolia* trees at this particular site had higher  $R_t$  is that the sampled individuals, reflective of the population within the plot, are generally shorter and in less dominant canopy positions compared to most other species (Fig. S4). The species, which is highly shade-tolerant, also has deep crowns (Anderson-Teixeira et al., 2015b), implying that

a lower proportion of leaves would be affected by harsher microclimatic conditions at the top of the canopy under drought (Fig. 3). Thus, the high  $Rt$  of the sampled *F. grandifolia* population can be explained by a combination of fairly drought-resistant leaf traits, shorter stature, and a buffered microenvironment.

Concerted measurement of tree-rings and leaf hydraulic traits of emerging importance (Scoffoni et al., 2014; Bartlett et al., 2016; Medeiros et al., 2019) allowed novel insights into the role of hydraulic traits in shaping drought response. The finding that  $PLA_{dry}$  and  $\pi_{tlp}$  can be useful for predicting drought responses of tree growth (Tables 1,4,5) is both novel and consistent with previous studies linking these traits to habitat and drought tolerance. Previous studies have demonstrated that  $\pi_{tlp}$  and  $PLA_{dry}$  are physiologically meaningful traits linked to species distribution along moisture gradients (Maréchaux et al., 2015; Fletcher et al., 2018; Medeiros et al., 2019; Simeone et al., 2019; Rosas et al., 2019), and our findings indicate that these traits also influence drought responses. Furthermore, the observed linkage of  $\pi_{tlp}$  to  $Rt$  in this forest aligns with observations in the Amazon that  $\pi_{tlp}$  is higher in drought-intolerant than drought-tolerant plant functional types and adds support to the idea that this trait is useful for categorizing and representing species' drought responses in models (Powell et al., 2017). Because both  $PLA_{dry}$  and  $\pi_{tlp}$  can be measured relatively easily (Bartlett et al., 2012; Scoffoni et al., 2014), they hold promise for predicting drought growth responses across diverse forests. The importance of predicting drought responses from species traits increases with tree species diversity; whereas it is feasible to study drought responses for all dominant species in most boreal and temperate forests (e.g., this study), this becomes difficult to impossible for species that do not form annual rings, and for diverse tropical forests. Although progress is being made for the tropics (Schöngart et al., 2017), a full linkage of hydraulic traits to drought responses would be invaluable for forecasting how little-known species and whole forests will respond to future droughts (Powell et al., 2017).

As climate change drives increasing drought in many of the world's forests (Trenberth et al., 2014; Intergovernmental Panel on Climate Change, 2015), the fate of forests and their climate feedbacks will be shaped by the biophysical and physiological drivers observed here. Large trees have been disproportionately impacted by strong drought in forests around the world (Bennett et al., 2015; Stovall et al., 2019), and we show, at least at this site, that this is primarily driven by their height, potentially with some contributions from crown position. The distinction is important because it suggests that height *per se* makes trees vulnerable, even if their crowns are somewhat protected by neighbors, whereas shorter solitary trees or the dominant trees in young forests that recently established after logging or natural disturbances should be less vulnerable. This would suggest that, all else being equal, mature forests would be more vulnerable to drought than young forests with short trees; however, root water access may limit the young forests (Bretfeld et al., 2018), and species traits often shift as forests age. Early- to mid- successional species at our site (*Liriodendron tulipifera*, *Quercus spp.*, *Fraxinus americana*) display a mix of traits conferring drought tolerance and resistance (Table 3), and further research on how hydraulic traits and drought vulnerability change over the course of succession would be valuable for addressing how drought tolerance changes as forests age (e.g. Rodríguez-Catón et al., 2015). In the meantime, the results of this study advance our knowledge of the factors conferring drought resistance in a mature forest, opening the door for more accurate forecasting of forest responses to future drought.

## Acknowledgements

We especially thank the numerous researchers who helped to collect the data used here, in particular Jennifer C. McGarvey, Jonathan R. Thompson, and Victoria Meakem for original collection and processing of cores.

Thanks also to Camila D. Medeiros for guidance on hydraulic and functional trait measurements, Edward Brzostek’s lab for collaboration on leaf sampling, and Maya Prestipino for data collection. This manuscript was improved based on helpful reviews by Mark Olson and three anonymous reviewers. Funding for the establishment of the SCBI ForestGEO Large Forest Dynamics Plot was provided by the Smithsonian-led Forest Global Earth Observatory (ForestGEO), the Smithsonian Institution, and the HSBC Climate Partnership. This study was funded by ForestGEO, a Virginia Native Plant Society grant to KAT and AJT, and support from the Harvard Forest and National Science Foundation which supports the PaleON project (NSF EF-1241930) for NP.

## Author Contribution

KAT, IM, and AJT designed the research. Tree-ring chronologies were developed by RH under guidance of AJT and NP. Trait data was collected by IM, JZ under guidance of NK and LS. Other plot data were collected by IM, AS, EGA, and NB under guidance of EGA and WM. Data analyses were performed by IM under guidance of KAT and VH. KAT and IM interpreted the results. IM and KAT wrote the first draft of manuscript, and all authors contributed to revisions.

## Supplementary Information

Table S1: Species-specific bark thickness regression equations

Table S2: Species-specific height regression equations

Table S3: Palmer drought severity index (PDSI) by month for focal droughts

Figure S1: Map of ForestGEO plot showing TWI and location of cored trees

Figure S2: Time series of Palmer Drought Severity Index (PDSI) for the 2.5 years prior to each focal drought

Figure S3: Height (from reconstructed DBH) by crown position across the three focal droughts and in the year of measurement (2018)
